INTRODUCTION

With the development of farming in the Pacific Coast States wheat became the dominant crop. At first most of the wheat was spring sown, and careful seed treatment kept the bunt, or stinking smut (*Tilletia tritici* (Bjerk.) Wint.), under control. When the growing of winter wheat became general, however, it was found that bunt was the most destructive disease of wheat in this region. This was largely owing to the fact that the spores of *T. tritici* live until winter in the soil in this region and bunt tends to increase from year to year.

The heavy annual losses of wheat caused by bunt combined with the ineffectiveness and expense of seed treatment and the possibility of seed injury point to the evident need of a more certain means of bunt control. The most promising possibility appears to be through the development of resistant varieties. Two methods of procedure

are possible: (1) To test as many wheats as are obtainable with the hope of finding varieties naturally resistant to bunt and (2) to use as parents such resistant varieties as may be found and so to develop by hybridization commercially desirable smut-resistant varieties.

This bulletin deals with the first phase of these investigations, namely, a study of a large number of varieties and selections of wheat with reference to their relative resistance to the bunt fungus which causes the principal losses west of the Rocky Mountains.

Acknowledgments are due Dr. George M. Reed, formerly Pathologist in Charge of Cereal-Smut Investigations, Office of Cereal Investigations, for general supervision of the experiments during 1919 and 1920. The writers are indebted to J. Allen Clark, Agronomist in Charge of Western Wheat Investigations, and V. H. Florell, Agronomist, Office of Cereal Investigations, and to agronomists of the agricultural experiment stations of California, Oregon, Washington, and Kansas for furnishing seed for these studies, and to J. C. Bell, Assistant Pathologist, Office of Cereal Investigations, for assistance in the experiments at Moro, Oreg.

The experiments, the results of which are reported herein, were conducted in cooperation with the State agricultural experiment stations of California, Oregon, and Washington. The investigation was planned and conducted by the following persons at their respective stations:

California.—Fred N. Briggs, Assistant Pathologist, Office of Cereal Investigations, and W. W. Mackie, Cerealist, California Agricultural Experiment Station, Berkeley, Calif., and Collaborator, Office of Cereal Investigations, Bureau of Plant Industry.

Oregon.—H. M. Woolman, Field Assistant in Plant Pathology, Office of Cereal Investigations, and D. E. Stephens, Agronomist and Superintendent, Sherman County Branch Station, Moro, Oreg., Office of Cereal Investigations.

Washington.—E. F. Gaines, Cerealist, Washington Agricultural Experiment Station, and Agent, Office of Cereal Investigations, and F. J. Stevenson, Agent, Office of Cereal Investigations.

W. H. Tisdale, Pathologist in Charge of Cereal-Smut Investigations, and J. H. Martin, Agronomist, Western Wheat Investigations, Office of Cereal Investigations, Bureau of Plant Industry, have been responsible for the final preparation of these data for publication.

PREVIOUS INVESTIGATIONS

Other investigators have studied the relative bunt resistance of a limited number of wheats during the past two decades.

Farrer (4)¹ reported the results obtained by him in 1900 from inoculating 10 varieties of wheat with spores of the bunt organism, the infection of different varieties ranging from 12 to 95 per cent. Additional results were reported by Farrer in 1904 (5). In 1901 he developed through hybridization two varieties of wheat, Florence and Genoa, which, according to Sutton (10), possessed a high resistance to bunt.

Tubeuf (11), working in Germany, in 1901 and 1902 studied the relative resistance of 23 varieties of wheat to bunt. None of them were totally resistant, but he found a wide range of difference in the degree of their resistance. The Ohio and Ontario varieties

¹ Numbers in italics in parentheses refer to "Literature cited," at the end of this bulletin.

remained almost bunt free, whereas others showed from 25 to 60 per cent of bunt. Kirchner (7) in 1908 reported the results of two to four years experiments in Germany with a large number of varieties, including 33 winter varieties of common wheat. Some of these remained almost bunt free, while others produced as much as 33 per cent of bunt.

Darnell-Smith (2), of Australia, after repeated experiments came to the conclusion that certain wheats have properties which render them immune from bunt. He mentions Cedar, Florence, and Medeah as being resistant, and states that they have little brush and a horny endosperm. McAlpine (8) reported the results obtained by several workers in Australia in determining bunt resistance of wheat varieties and hybrids.

Gaines (6), of the Washington Agricultural Experiment Station, reported in 1918 the results of his studies of the comparative bunt resistance of 13 varieties of commercial wheat. He found the Turkey and Alaska varieties to be highly resistant to this disease. Others were more or less highly susceptible.

In 1921 Donkin (3), of South Africa, reported the results of experiments in 1918 and 1919 to determine the relative bunt resistance of 20 varieties, including all types of wheats grown in South Africa. He included in his experiments three varieties of durum wheat (*Triticum durum*), three of Polish wheat (*T. polonicum*), two of poulard wheat (*T. turgidum*), one of club wheat (*T. compactum*), and 11 of common wheat (*T. vulgare*), the last consisting of bearded and beardless and early and late varieties. Practically all except the common wheats remained bunt free. One variety of durum wheat, Wild Goose (Arnautka), had 2 per cent of bunt in 1918 in plants cut back when the culms began to form. Among the common wheats Rieti showed an average of 3 per cent of bunt, and other varieties showed 14 to 36 per cent.

PRESENT INVESTIGATIONS

LOCATION AND SCOPE

Preliminary experiments on bunt resistance conducted at the Sherman County Branch Station, Moro, Oreg., in 1918, with the results previously obtained at the Washington station, are the bases for the present investigations.

Experiments were begun, therefore, in the fall of 1918 at Moro and at Pullman, Wash., in cooperation with the Oregon and Washington Agricultural Experiment Stations, to determine on a large scale the relative resistance of wheat varieties to the bunt fungus. These experiments included practically all the commercial wheats of the United States, as well as numerous other varieties and pure-line selections assembled in the wheat-classification nurseries of the Office of Cereal Investigations.

In 1919 the experiments were also confined to Oregon and Washington. The seed of the wheat varieties sown in the classification nurseries at Moro and Pullman in the fall of 1918 was smutted with spores of *Tilletia tritici*. These experiments included 455 varieties and pure-line selections at Moro and 186 at Pullman. Seed of numerous varieties of wheat from Australia and India and about 134

selections of hard red winter wheat also was inoculated, and the plants were grown in the nurseries at Moro in 1919.

In 1920 experiments were conducted in California as well as in Oregon and Washington, and were continued in California in 1921. Artificially smutted seed of the above-mentioned varieties and selections, together with that of additional ones, was sown at Moro, Oreg., Pullman, Wash., and Davis, Calif. Many of the Australian and Indian wheats also were grown in this season. At Davis about 950 varieties and selections were sown. The experiments at Moro were somewhat less extensive, and still fewer varieties and selections were sown at Pullman.

These experiments were continued for two years at each of the three stations, and as nearly as possible the same varieties were included in the sowings at all points. Many of the data obtained at Moro have been published by Stephens and Woolman (9) in a bulletin issued by the Oregon Agricultural Experiment Station. Sowings of a limited number of these wheats were made at Corvallis, Hermiston, and Union, Oreg., for the purpose of determining the effects of local conditions on bunt infection. These latter data are not given in the tables because the results obtained did not permit the drawing of accurate conclusions.

METHODS

The seed of these numerous varieties and pure-line selections to be sown at the different stations was obtained as far as possible from identical seed lots and then heavily smutted with spores of *Tilletia tritici* before sowing. The seed, together with dry spores produced in the previous year, was thoroughly shaken in a closed container until the surface of each kernel had a dark smutty appearance. The seed was sown then in single, duplicated, or triplicated rows about 1 foot apart. The sowings were made at each station as nearly as possible at the time when conditions would be conducive to maximum infection. This time, of course, varied considerably, depending on the locality and existing weather conditions. At Davis there was considerably more bunt in these wheats in the crop of 1920 than in that of 1921. This no doubt was caused by the difference in weather conditions at the time of sowing.

In determining the percentages of bunt, counts of the smutted heads and of total heads were made and the percentage of bunt calculated from these figures. In most cases both plant and head counts were made, but the percentages given in the tables in this bulletin are based on head counts only, as these figures seem to indicate more accurately the actual damage caused by the disease.

A list of the varieties and selections grown at Davis, Moro, and Pullman, showing the percentages of bunt infection, is given in Table 1. The list does not include the Australian, Indian, and South African wheats, which are given in Tables 4, 5, and 6, or a number of selections from White Australian.

Most of these wheats were grown during two years. Lack of funds prevented the continuation of these experiments for a longer period. However, results for two years at these widely separated stations should be sufficient to furnish a fairly satisfactory indication of the relative resistance of these wheats to bunt. When a variety or selec-

tion shows bunt infection under any condition it is known to be not immune, and such varieties as are not immune or highly resistant are not considered worthy of continued testing. Immune or highly resistant varieties should be subject to conditions as favorable as possible for bunt infection in order to determine their degree of resistance. These are the wheats desired to serve as resistant parent stocks for hybridization studies.

RESULTS WITH AMERICAN WHEATS

The results obtained in bunt experiments with American wheat varieties and selections are presented in Tables 1 to 4, inclusive. Data on commercial varieties of common wheat are given in Table 1, but results with selections of hard red winter wheat and a few results on head selections of Pacific Bluestem, a white wheat, are given in the text only.

Full data on a few of the most bunt resistant of the selections of hard red winter wheat are presented later in Table 8, under the heading "Resistant varieties."

Data similar to those for common wheat are presented for club wheats in Table 2 and for durum wheats in Table 3. Results of experiments on minor wheat groups, such as emmer, spelt, poulard wheat, Polish wheat, and einkorn, are shown in Table 4 and the accompanying text.

COMMON WHEATS

In preparing the data the common wheats are separated into "Commercial varieties" (Table 1) and "Selections" (not tabulated).

COMMERCIAL VARIETIES

The percentages of infected heads in the commercial American varieties of common wheat are shown in Table 1. The common wheats are here divided into four commercial classes (hard red spring, hard red winter, soft red winter, and white). The recognized varieties are listed in alphabetical order, following the nomenclature used in the "Classification of American Wheat Varieties," by Clark, Martin, and Ball (1). All names of synonymous varieties are listed together in alphabetical order or in the order of their Cereal Investigations (C. I.) numbers under the recognized varietal names. Data are shown for only the varieties and selections which have been grown in the bunt experiments during two or more station years.

The varieties consist largely of those assembled for the study of wheat classification by members of the Office of Cereal Investigations. Many were grown from seed selected from individual heads in previous seasons and thus are pure-line selections, whereas others represent merely the mass variety. It may be possible, therefore, that other pure lines of these varieties would show different degrees of bunt infection. Two or more strains of nearly all varieties were grown in the bunt experiments, so that the behavior of the variety as a whole is fairly well indicated.

TABLE 1.—*Classified list of common wheats, chiefly commercial American varieties, grown at Davis, Calif., Moro, Oreg., and Pullman, Wash., showing the percentages of heads infected with bunt in two or more of the years specified*

The data in Table 1 show that nearly all varieties of common wheat are very susceptible to bunt. There is a difference, however, in the degree of resistance possessed by the groups of common wheats when each is considered as a whole. The data are not strictly comparable but are doubtless indicative. The hard red winter wheats are the most resistant, showing an average infection of 22.7 per cent, and the white wheats and the soft red winter wheats with average infections of 60.2 and 58.8 per cent, respectively, are the least resistant. The hard red spring wheats showed an average bunt infection of 50 per cent.

Within each group are found one or more varieties or selections that are highly resistant to bunt. There is a greater number of such resistant varieties in the hard red winter group than in any other, but a few of the more susceptible strains are about as subject to bunt as any of those found in the other groups of common wheat. The very susceptible hard red winter varieties, Alton and Eureka, are awnless and of little commercial importance. If these were omitted the remaining varieties, all belonging to the awned Crimean group and comprising almost all of the commercial hard red winter wheats, would show an average infection of only 10.9 per cent. This is less than that of any other class or species of wheat except einkorn.

Of the entire list of common wheats which were grown in all three States for two years only two remained bunt free. These were Hussar (Red Hussar), C. I. No. 4843, a hard red winter wheat, and Martin (Martin Amber), C. I. No. 4463, a white wheat.

None of the hard red spring wheats was especially resistant to bunt, although Ruby had an average bunt infection of only 11.5 per cent.

Besides Hussar, which was immune, other hard red winter wheats showing a high degree of resistance are Minturki (C. I. No. 6155), Kanred (P-1066 and P-1068), and Rieti (C. I. No. 2578).

Two strains of Odessa (C. I. Nos. 4473 and 6035) were the only soft red winter wheats showing distinct resistance to bunt, and these were grown only at Davis.

Besides Martin, which was immune, other white wheats showing a high degree of resistance were White Odessa (C. I. No. 4481-C), which had an average of 0.2 per cent bunt, and other selections of the same variety (C. I. Nos. 4651 and 4655), which were infected only 1.1 and 2.4 per cent, respectively.

SELECTIONS

In 1916 at Moro, 134 selections of hard red winter wheat were grown in the classification nursery. These were tested for yield in the nursery at Moro in 1917 and 1918 and were sown in the bunt experiments in the fall of 1918. The complete results are not tabulated, but several of the selections proved somewhat resistant to bunt.

Detailed data are shown later (Table 8) for eight of the most resistant of these selections, which were continued in the experiments during the three seasons following.

In the season of 1919-20 seed from 168 head selections of Pacific Bluestem (White Australian) wheat was smutted with spores of *Tilletia tritici* and sown in the experiments at Davis. The original head selections were collected from a large number of fields in the Sacramento Valley in 1917 by J. Allen Clark and E. L. Adams, of the Office of Cereal Investigations. They were grown in the nursery at Chico, Calif., where the seed for these experiments was obtained. The results from this single season's experiments show little probability of finding bunt-resistant strains of this variety through head selection. The lowest percentage of bunt in any selection was 78, and most of them showed more than 90 per cent of infection.

CLUB WHEATS

Data showing the results obtained with club wheats are presented in Table 2. These wheats had an average infection of 68.4 per cent and therefore are highly susceptible to bunt. As a group the varieties are more uniformly susceptible than are the common wheats. The lowest percentage of bunt shown by any variety or selection was 9.2 per cent, by a field selection (C. I. No. 4669) which closely resembles Hybrid 3. The next lowest percentage, 32.3, was shown by Hybrid 3 (C. I. No. 4239).

DURUM WHEATS

The durum wheats as a group are more bunt resistant than the common and club wheats, except the hard red winter varieties, but showed an average infection of 33.1 per cent (Table 3). There is a wide range of susceptibility, however, between varieties within the group. Kubanka (C. I. No. 2909) and Velvet Don (C. I. No. 2222) in limited tests showed high resistance, but none was bunt free.

MINOR WHEAT GROUPS

Results of the bunt experiments with the minor wheat groups, such as emmer, spelt, poulard wheat, Polish wheat, and einkorn, are given below. Data for the first three of these are given in Table 4.

The data for emmer show that the varieties grown bore 18.5 per cent of infected heads. Emmer is more resistant than common, club, durum, or poulard wheat.

The data in Table 4 show that spelt apparently is slightly more resistant to bunt than emmer. The varieties grown showed an average of 15.9 per cent of infection.

Such poulard wheats as were grown proved more or less susceptible and showed an average infection of 29.8 per cent. Winter Alaska (C. I. No. 5873) showed the least amount of bunt, 6.2 per cent.

Only one variety of Polish wheat (C. I. 3007) was included in these experiments. It was grown for two years at Davis and Pullman. At Davis it had 37.3 per cent of bunt in 1920 and 12.1 per cent in 1921. At Pullman it showed 1.8 per cent of infection in 1919 and 27.4 per cent in 1920. It averaged 19.7 per cent of infection in the four station years grown.

Einkorn (C. I. 2134) was grown at only one station, Pullman, where it remained bunt free in both years. In experiments conducted by one of the writers (W. W. Mackie) at Berkeley, Calif., in 1919, einkorn showed about 25 per cent of infection.

RESULTS WITH AUSTRALIAN WHEATS

Many Australian wheats, principally spring common varieties, were included in the experiments at Davis and Moro. These wheats were grown during two years at Davis and only one year at Moro. The same methods were employed in smutting the seed, sowing, and calculating the percentages of bunt as were used with all other wheats. The results are given in Table 5.

According to the results of the limited experiments presented in Table 5, these Australian wheats appear to be rather uniformly susceptible to bunt. A few varieties, however, show a marked degree of resistance. Among these are Florence (C. I. Nos. 4170, 4988, and 4740), Genoa (C. I. No. 4120), Bathurst No. 2 (C. I. No. 4116), Nardoo (C. I. No. 4985), all common wheats, and the only poulard wheat included in the list, Marster's Perfection (C. I. No. 4726). None of these, however, with the exception of Florence, shows enough resistance, combined with other desirable qualities, to make it highly desirable for use as a parent for hybridization purposes.

RESULTS WITH INDIAN WHEATS

Seed of a number of selections of Indian wheats was smutted with spores of *Tilletia tritici* and sown at Moro, Oreg., from March 28 to April 9, 1919. Most of these selections became heavily infected in these trials, and none were free enough from bunt to indicate any marked degree of resistance. One selection, C. I. No. 4909, had only 12 per cent of infection. The remainder of these selections showed 34 per cent or more of bunt and are grouped in the following list by their Cereal Investigations (C. I.) numbers according to percentages of infection.

Indian wheat varieties grown at Moro, Oreg., in 1919, listed under their Cereal Investigations numbers and grouped according to percentages of bunted heads

From 34 to 50 per cent infection.—4533, 4561, 4691, 4698, 4699, 4911, 4919.

From 51 to 75 per cent infection.—4527, 4532, 4548, 4549, 4559, 4562, 4563, 4690, 4692, 4695, 4697, 4700, 4702, 4703, 4902, 4905, 4907, 4908, 4910, 4912, 4913, 4914, 4915, 4920, 4921, 4925, 5432, 5438.

From 76 to 96 per cent infection.—4067, 4525, 4526, 4528, 4530, 4531, 4534, 4535, 4536, 4537, 4538, 4539, 4540, 4541, 4542, 4543, 4544, 4545, 4546, 4547, 4550, 4551, 4552, 4553, 4554, 4555, 4556, 4557, 4558, 4564, 4693, 4694, 4696, 4701, 4704, 4901, 4904, 4906, 4916, 4917, 4918, 4922, 4923, 4924, 4926, 5411, 5412, 5413, 5414, 5415, 5416, 5417, 5418, 5419, 5420, 5421, 5422, 5423, 5425, 5426, 5427, 5428, 5429, 5430, 5433, 5434, 5435, 5436, 5437, 5439, 5440, 5441, 5443, 5446, 5447, 5449, 5450, 5453, 5461, 5462, 5466, 5468, 5470, 5471.

The results show that these wheats are highly susceptible to bunt and that it will not be an easy matter to find resistant strains among them. As they are not grown commercially in the United States, it will not be desirable to give them further consideration here.

RESULTS WITH SOUTH AFRICAN WHEATS

Twenty-eight varieties of wheat obtained from different parts of South Africa were grown in the bunt experiments at Davis, Calif., in 1920 and 1921. An unnamed variety, C. I. No. 6165, showed the lowest average infection, 22.5 per cent. All other varieties showed 40 per cent or more. The data are presented in Table 6.

RESULTS WITH MISCELLANEOUS WHEATS

Some selections and varieties have been included in these experiments which do not belong to any of the groups for which tabulated data have been presented. They are not commercial American varieties or varieties from Australia, India, or South Africa. They comprise selections and hybrids made in this country and a few foreign wheats.

Table 7 presents the detailed percentages of infection in these wheats. Most of them are very susceptible. Six hybrid selections show high resistance in a 2-year experiment at Davis, Calif. Three hybrids resulting from a cross between Turkey and Hybrid 128 are very resistant, while three derived from a cross between Turkey and Florence, a resistant Australian wheat, are immune or nearly so. Ridit (see Table 8), the highly resistant commercial hybrid being distributed from the Washington Agricultural Experiment Station, was derived from the cross between Turkey and Florence.

TABLE 7.—Percentages of infected heads in miscellaneous selections and hybrids of American wheat varieties and a few foreign varieties at Davis, Calif., Moro, Oreg., and Pullman, Wash., in the years specified

RESISTANT WHEAT VARIETIES

The extensive experiments on bunt resistance in commercial varieties of American wheats presented in Tables 1 to 4, inclusive, have shown a few varieties and selections to be either immune from or very resistant to the attacks of *Tilletia tritici*. As these have the promise of much economic importance, either for commercial production or for use as parents in breeding experiments, a brief account is given of each.

These wheats belong to three of the five different commercial classes, namely, (1) Hard Red Winter, (2) Soft Red Winter, and (3) White. Hussar, an immune variety (Table 1); Sherman and several other selections from Turkey (Table 8); and Redit, resulting from a hybrid between Turkey and Florence (Table 8), are hard red winter wheats. Banner Berkeley (Table 8) is a soft red winter wheat. Florence, a commercial Australian variety (Table 8); Martin, another immune selection (Tables 1 and 8); and the strains of the so-called

White Odessa (Tables 1 and 8) are white wheats. There were no outstanding resistant varieties or selections in the Hard Red Spring and Durum classes, and the problem of developing resistant commercial wheats in these classes apparently is more difficult.

Only two of the resistant wheats mentioned here, Florence and Redit, were bred especially for bunt resistance. The others originated from selections made for other purposes. The discovery of their bunt resistance resulted from the experiments presented herein.

Table 8 contains the detailed results of the experiments with the immune and resistant varieties during two years at Davis, Calif., and during four years for most varieties at Moro, Oreg., and for a few varieties at Pullman, Wash.

TABLE 8.—Percentages of bunted heads produced by the most resistant varieties and selections of hard red winter, soft red winter, and white wheats grown at Moro, Oreg., Davis, Calif., and Pullman, Wash., in one or more years during the period specified

HARD RED WINTER WHEATS

Hussar (Red Hussar; C. I. No. 4843) is a pure-line selection made from a plat of Hussar wheat at the Illinois Agricultural Experiment Station by C. E. Leighty in 1913. It has proved immune from bunt in all experiments. The original Hussar variety is of undetermined origin, but had been grown at the Illinois station since 1905. It is not very resistant to bunt, as it showed 10 per cent of infection at Moro, Oreg., in 1921.

The selected Hussar is an awned hard red winter wheat having kernels slightly larger and softer than Turkey. The spikelets are easily shattered at maturity. It is of good bread-making quality but has yielded less than several other hard red winter wheats. Because of its immunity from bunt in the Pacific Coast States it is being used as a parent in breeding for bunt-resistant wheats.

Sherman (C. I. No. 4430) is a recently named strain selected by J. Allen Clark from a plat of Turkey wheat at Moccasin, Mont., in 1915. It is similar to Turkey except that it is slightly earlier and taller, has lighter green leaves, the spikes are larger, and the kernels shatter more easily. When grown at Moro this variety appears to be about equal in yield and quality to Turkey, and if later tests confirm these results it can profitably replace Turkey and Kharkof because seed treatment will not be necessary.

HARD RED WINTER SELECTIONS

Several of the most resistant of these selections (Table 8) are typical Turkey in all characters except bunt resistance. Sherman (C. I. 4430), previously described, is one of the most promising of these selections. Other noteworthy selections are Nos. 1558-A, 7367 (1558-B), 7363 (1571-C), and 7366 (3055-A), all of which were pure-line selections made at the Moro station by Carleton R. Ball. Selection Nos. 2576-A and 2903-5 were made at the Amarillo Cereal Field Station, Amarillo, Tex., the former by J. Allen Clark and the latter by Louis Wermelskirchen. Selections of this character promise to replace the ordinary Turkey and Kharkof wheats in sections where bunt is a serious menace, because they can be sown without seed treatment.

Ridit (C. I. No. 6703; Washington No. 2324) is a selection from a hybrid between Turkey and Florence made by E. F. Gaines at the Washington Agricultural Experiment Station. It is an awnless hard red winter wheat with glabrous white glumes. It is the most promising of several selections from the above hybrids which were tested for yield and bunt resistance. It has shown only a trace of bunt in these experiments, and its yields in nursery trials at Pullman also are high.

SOFT RED WINTER WHEATS

Banner Berkeley (C. I. No. 7362) is the result of a hybrid made in 1912 at the Michigan Agricultural Experiment Station between Goldcoin (American Banner) and Turkey (Berkeley). It is a winter wheat having awnless spikes, glabrous white glumes, and soft red kernels. It proved markedly resistant to bunt, and selections made from it by H. M. Woolman appear to be immune. It has given rather low yields in limited experiments.

WHITE WHEATS

The Florence variety was originated by the late William Farrer, of New South Wales, Australia, by complex crosses involving the White Naples, Improved Fife, and Eden varieties. It was developed for its resistance to bunt and was first distributed in Australia about 1907. Florence is a spring wheat having awnless spikes with glabrous white glumes and rather hard white kernels. It is very resistant to bunt but has not proved well adapted in this country. Its value in hybridization is indicated by the highly resistant and immune strains (Table 8) isolated from crosses between Florence and Turkey by the Washington Agricultural Experiment Station.

Martin (Martin Amber; C. I. No. 4463) is a strain apparently identical with the commercial lots of the Martin variety except in being immune from bunt. It originated from a plant selected from a field of wheat near Arbon, Idaho, by Carleton R. Ball in 1915. It is

a tall midtime or late winter wheat having awnless, long, lax, nodding heads and soft white kernels. It is not especially productive or of high quality but is of promise in developing awnless or white-kerneled wheats resistant to bunt.

The so-called White Odessa differs from the Odessa variety principally in having white kernels. It possibly originated from natural hybridization between Odessa and a white-kerneled wheat, possibly Martin Amber. Wheats similar to White Odessa commonly occur as mixtures in fields of Odessa. Three strains of White Odessa were found which showed pronounced resistance to bunt. The one designated as 4481-C was developed from a plant selected from a field of Defiance wheat in Bannock Valley, Idaho, by Carleton R. Ball in 1915. The other two strains were selected from fields of wheat near Preston, Idaho. C. I. No. 4651 was obtained by a member of the Office of Grain Standardization of the Bureau of Markets, United States Department of Agriculture, in a field of mixed wheat, and C. I. No. 4655 by the Franklin County (Idaho) agricultural agent, Mr. Morrison, in a field of Lofthouse wheat.

White Odessa is somewhat late and has awnless tapering spikes with glabrous brown glumes and soft white kernels. It is rather winter hardy.

SUMMARY

Bunt causes severe losses to the wheat crop, especially in the Pacific Coast States. In that region seed treatment often is ineffective in controlling bunt because of soil infestation, and the standard liquid treatments frequently cause losses due to seed injury. The growing of wheats immune from bunt would prevent these losses and save the trouble and expense of seed treatment.

Seed of one or more strains of nearly all of the commercial varieties of wheat grown in the United States was smutted with spores of *Tilletia tritici* and sown during two years in nurseries at Davis, Calif., Moro, Oreg., and Pullman, Wash. Numerous foreign wheats and selections from other domestic varieties also were grown in these bunt experiments.

Nearly all varieties of American wheats, all but one of the Australian wheats, and all of the Indian and South African wheats are more or less susceptible to bunt.

Of the four commercial classes of common wheat, the hard red winter wheats are the most resistant, and the white wheats as a class are the most susceptible, although one variety and four selections proved to be immune or highly resistant. The hard red spring and soft red winter varieties are somewhat intermediate in susceptibility. One of the soft red winter varieties, however, proved to be highly resistant.

The club wheats as a group are the most susceptible to bunt. The durum, Polish, and poulard wheats as well as emmer and spelt in general are somewhat more resistant than the common wheats except hard red winter, which is more resistant than durum and poulard. Einkorn in these experiments developed no infection, though in some studies conducted at Berkeley in 1919 it showed 25 per cent of bunt.

Only two common wheats, Hussar (C. I. 4843) and Martin (C. I. 4463), proved immune from bunt in these experiments. Three

strains of White Odessa, nine selections from Turkey, and the Ridit, Florence, and Banner Berkeley varieties are highly resistant to bunt.

The immune strains of Hussar and Martin are of great promise for the development of bunt-resistant wheats by hybridization, although they are, in themselves, of little commercial value.

Limited yield experiments with Ridit, a hybrid between Turkey and Florence, indicate a possibility of its becoming a valuable commercial variety.

The resistant selections of Turkey, including one recently named Sherman, can safely be sown without seed treatment. These selections appear to be practically equal to the original Turkey in yield.
